Acknowledgements

Useful and detailed feedback was obtained on an earlier version of the document from more than 130 national tuberculosis and HIV programme managers, WHO regional and country staff, researchers, clinicians, nongovernmental organizations and other health workers from all regions through global web-based consultations. All leading international organizations working on tuberculosis, including the International Union Against Tuberculosis and Lung Disease (UNION), the Programme Advisory Group for TB (PAG) of KNCV, the German Leprosy and TB Relief Association and the Damien Foundation have also provided their comments on the earlier version. The document was reviewed by members of the Core Group of the global TB/HIV Working Group of the Stop TB Partnership and the Strategic and Technical Advisory Group for Tuberculosis (STAG-TB) and the Strategic and Technical Advisory Committee for HIV (STAC-HIV) of the World Health Organization.

Valuable comments were also provided by the following individuals: Raimond Armengol (Pan American Health Organization), Ramzi Asfour (WHO Headquarters), Daniel Chin (WHO, China), Mirtha Del Granado (Pan American Health Organization), Reuben Granich (Office of the Global AIDS Coordinator, United States of America), Christy Hanson (USAID, United States of America), Michael Kimerling (University of Alabama, United States of America), Nani Nair (WHO Regional Office for South-East Asia), Lisa Nelson (Centers for Disease Control, United States of America), Wilfred Nkhoma (WHO Regional Office for Africa), Pilar Ramon-Pardo (Pan American Health Organization), Mario Raviglione (WHO Headquarters), Fabio Scano (WHO Headquarters), Akhiro Seita (WHO Regional Office for the Eastern Mediterranean), Sahu Suvanand (WHO, India), Patrick van der Stuyft (Institute of Tropical Medicine, Belgium), Marco Vitoria (WHO Headquarters), Fraser Wares (WHO, India).

PART I

Improving the diagnosis and treatment of smear-negative tuberculosis
Background
Rates of smear-negative pulmonary and extrapulmonary tuberculosis have been rising in countries with HIV epidemics. The mortality rate among HIV-infected tuberculosis patients is higher than that of noninfected tuberculosis patients, particularly for those with smear-negative pulmonary and extrapulmonary tuberculosis. Delayed diagnosis may be an important cause of excess mortality in people living with HIV who have smear-negative pulmonary and extrapulmonary tuberculosis. In the absence of rapid, simple, and accurate diagnostic tools for smear-negative pulmonary and extrapulmonary tuberculosis, diagnostic algorithms have been recommended. Earlier algorithms and recommendations have been developed through consensus and expert opinion, without a firm evidence base. These algorithms extend a patient's evaluation over a period of time, during which HIV-infected patients may die from undiagnosed tuberculosis or from advanced HIV complications. The Stop TB Strategy now emphasizes the timely diagnosis and treatment of all cases of tuberculosis, including smear-negative pulmonary and extrapulmonary tuberculosis.

The existing guidelines for diagnosis of smear-negative pulmonary tuberculosis were published by WHO in 2003 (1) and codified in 2006 in the International standards for tuberculosis care (2), a publication of organizations, including WHO, which are members of the Stop TB Partnership. The International standards generally maintained the 2003 WHO recommendations, but recognize the importance of “flexibility” when applying these guidelines to smear-negative patients who are seriously ill, such as patients with HIV infection. It also highlights the absence of evidence showing how well these guidelines perform in HIV-infected patients.

Target audience
This document is intended for those dealing with tuberculosis and HIV at all levels in HIV-prevalent and resource-constrained settings. It is intended to assist development of national policies to improve the diagnosis and management of smear-negative pulmonary and extrapulmonary tuberculosis. The recommendations and algorithms are designed for use by national tuberculosis and HIV/AIDS control programmes and service providers. HIV-prevalent settings are defined as countries, subnational administration units (e.g. districts, counties) or selected facilities (e.g. referral hospitals, drug rehabilitation centres) where the adult HIV prevalence rate among pregnant women is ≥1% or HIV prevalence among tuberculosis patients is ≥5%. In those countries where national HIV prevalence is below 1%, national tuberculosis and HIV control authorities should identify and define HIV-prevalent settings (subnational administrative units or facilities) based on the epidemiology of the HIV epidemic and the magnitude of HIV-associated tuberculosis, and develop appropriate guidance for the implementation of these recommendations. The recommendations and revised algorithms are intended for immediate implementation in sub-Saharan Africa and other HIV-prevalent settings, as defined by national tuberculosis and HIV control authorities, to guide the expedited diagnosis and management of tuberculosis.

Process of formulation
In September 2005, WHO convened an expert group to review currently recommended approaches to the diagnosis of smear-negative tuberculosis in HIV-prevalent settings and to propose revisions to existing WHO guidelines. The Expert Group has reviewed existing evidence in each of the relevant areas and made recommendations and has revised the existing diagnostic algorithms. The recommendations and revised diagnostic algorithms were then posted on the WHO Stop TB Department’s web site for an open consultation. Feedback was obtained from national programme managers, researchers, clinicians and other health workers throughout the world, and from all the leading international organizations working on tuberculosis. The Expert Group subsequently revised the recommendations and algorithms in the light of the feedback from the global consultation and from presentations at various international scientific meetings. The Strategic and Technical
Advisory Group for Tuberculosis (STAG-TB) and the Strategic and Advisory Committee for HIV (STAC-HIV), the two independent bodies that advise WHO on tuberculosis and HIV respectively, endorsed the recommendations.

**Strength of the recommendations**

The recommendations contained in these guidelines are based on evidence from randomized clinical trials, high-quality scientific studies, observational cohort data and, where sufficient evidence is not available, on expert opinion (see Table 1). When appropriate, the level of evidence used to formulate the recommendations is included in the text of the document and shown in Table 1. The strength of each recommendation is stated when appropriate, along with the level of evidence, to provide a general indication of the extent to which regional and country programmes should consider implementing the recommendations.

For example, a recommendation marked as A II is a recommendation that should be followed and is based on evidence from at least one high-quality study or several adequate studies with clinical, laboratory or programmatic end-points. Those recommendations which are based on well established clinical practice are presented as such, without any indication of the level of evidence. For example, the recommendation that calls for an increased level of clinical awareness and competence in managing extrapulmonary tuberculosis at first-level health facilities is not linked with a particular level of evidence. The recommendations do not explicitly consider cost-effectiveness, although the realities of burden of disease, human resources, health system infrastructure and socioeconomic issues need to be taken into account when adapting these recommendations to regional and country programmes.

**Implementation and evaluation**

In the absence of complete evidence, the recommendations were built on consensus and iterative global expert opinion. It is believed that they will provide a reasonable response to the catastrophe posed by the dual tuberculosis and HIV epidemics. These recommendations should, therefore, be implemented in HIV-prevalent settings in order to improve and expedite the diagnosis of tuberculosis among people living with HIV. The implementation of the recommendations requires a reasonably efficient health system, including quality assurance for laboratories and effective supply management and training for programme staff. Moreover, depending on country-specific-factors, it may require revision of national guidelines, logistic and technical arrangements including human resources, training and infrastructure development. While the recommendations are being implemented, it is essential to build up the evidence base required to assess their effectiveness and feasibility. Careful evaluations by national authorities, research groups and interested parties are needed to assess the likely benefits and responsiveness of the recommendations for the dual tuberculosis and HIV epidemics. The findings of these evaluations will inform policy.

change designed to improve programme performance both globally and nationally. A protocol that provides generic guidance on evaluation of the recommendations to improve the diagnosis of tuberculosis in HIV-prevalent settings is annexed to this document.

Recommendations
Revised case definitions
The following are suggested case definitions for use in HIV-prevalent settings:

**Smear-positive pulmonary tuberculosis**
- One sputum smear examination positive for acid-fast bacilli (AFB) and
- Laboratory confirmation of HIV infection or
- Strong clinical evidence of HIV infection.

**Smear-negative pulmonary tuberculosis**
- At least two sputum specimens negative for AFB and
- Radiographical abnormalities consistent with active tuberculosis and
- Laboratory confirmation of HIV infection or
- Strong clinical evidence of HIV infection and
- Decision by a clinician to treat with a full course of antituberculosis chemotherapy
  - OR
  - A patient with AFB smear-negative sputum which is culture-positive for *Mycobacterium tuberculosis*.

**Extrapulmonary tuberculosis**
- One specimen from an extrapulmonary site culture-positive for *Mycobacterium tuberculosis* or smear-positive for AFB
  - OR
- Histological or strong clinical evidence consistent with active extrapulmonary tuberculosis and

1 Depending on clinical assessment and national and/or local policy, a person of unknown HIV status may be classified as HIV-positive for the purposes of diagnosis and management.

- Laboratory confirmation of HIV infection or
- Strong clinical evidence of HIV infection and
- A decision by a clinician to treat with a full course of antituberculosis chemotherapy.

**Strength of recommendation: A**

Antibiotics trial

**Context:** There is limited evidence for the use of empirical antibiotic treatment to rule out tuberculosis as a cause of cough in HIV-infected persons. Although non-response to antibiotics increases the likelihood of tuberculosis, the converse is not true; response to antibiotics does not exclude tuberculosis in tuberculosis suspects living in HIV-prevalent settings. Inappropriate use of broad-spectrum antibiotics may also lead to drug resistance, treatment delay and death of patients because of prolonged symptoms.

**Recommendations:**
- The primary role of antibiotics should not be as a diagnostic aid; they should be used to treat concomitant bacterial infection in people living with HIV/AIDS with cough or serious illness (Strength: A–IV).
- Antibiotic treatment is appropriate for HIV-infected patients with cough, because bacterial infections are common both with and without tuberculosis (Strength: A–II).
- Seriously ill patients with symptoms suggestive of tuberculosis should be treated empirically with broad-spectrum antibiotics because the benefits outweigh the risks (Strength: A–II).
- When indicated, one course of broad-spectrum antibiotics, including coverage for typical and atypical causes of community-acquired pneumonia, should be used to reduce the time delay for tuberculosis diagnosis (Strength: A–IV). In such circumstances, fluoroquinolones should be avoided, as they may cause undue delay in the diagnosis of tuberculosis (Strength: A–II).
- More research about the effectiveness and use of an antibiotic trial in the diagnostic algorithm and the choice of antibiotics, par-
ticularly for people living with HIV, is needed (Strength: A).

Chest radiograph

Context: Although chest X-ray abnormalities are common in HIV-infected persons without tuberculosis, the chest X-ray plays an important role in the diagnosis of tuberculosis among people living with HIV. The chest X-ray can also be an important entry point to diagnosing non-tubercular chest diseases, which are common among people living with HIV.

Recommendations:

- Chest X-ray presentations of tuberculosis in HIV patients are now well characterized and should no longer be considered “atypical” for tuberculosis in HIV-prevalent settings (Strength: A–IV).
- Chest X-rays play a significant role in shortening delays in diagnosis and should be performed early in the course of investigation of a tuberculosis suspect (Strength: A–II).
- Sound clinical judgement is needed to put a seriously ill patient with negative sputum smear results on antituberculosis treatment using only suggestive radiographical findings. In such circumstances, the clinical response of the patient has to be monitored and tuberculosis diagnosis should be confirmed at least by clinical response to antituberculosis treatment and preferably by culture (Strength: B–II).
- The limitations that exist on the wider use of chest X-rays, such as nonavailability at peripheral health facilities and the difficulty of interpreting results, even by trained physicians, need to be addressed, including through training (Strength: A).
- Research is needed to identify innovative ways to enhance the ability of clinicians, including nonphysicians, to interpret chest X-rays accurately, to assess the feasibility and added value of peer reviewing of chest X-rays and to evaluate novel imaging techniques that might replace conventional radiography (Strength: A).

Sputum culture

Context: Sputum culture is the gold standard for the diagnosis of tuberculosis. However, mycobacteria are slow-growing organisms and culture takes several weeks and requires relatively sophisticated facilities and technical expertise. Sputum culture of HIV-infected individuals requires more incubation time than for non-HIV-infected patients, although it is still of value. There are major challenges to ensuring access to high-quality sputum culture in HIV-prevalent and resource-constrained settings.

Recommendations:

- Careful feasibility studies are needed, particularly for liquid culture systems that are more sensitive and rapid than solid culture, and have the potential for expanded use, including in HIV-prevalent and resource-limited settings (Strength: A–II).
- In patients with negative sputum smears, sputum culture should be encouraged as part of the diagnostic procedure for people living with HIV who are being evaluated for AFB smear-negative tuberculosis, since it will improve the quality of care and assist the confirmation of the diagnosis (Strength: A–I).
- Existing capacity for the use of conventional culture systems in countries should be explored, encouraged and strengthened. Decentralization of sputum culture services with an efficient quality assurance system is essential. Establishment of an effective transport system for sputum is also essential (Strength: A).

Immune reconstitution inflammatory syndrome (IRIS) and tuberculosis diagnosis

Context: Immune recovery usually occurs rapidly in HIV-infected adults who are started on antiretroviral treatment (ART). Occasionally, recovery of the immune system leads to clinical signs and symptoms of active tuberculosis. This may be because patients had subclinical tuberculosis before the antiretroviral treatment began, or because a latent tuberculosis infection has been reactivated. The condition, which is
known as immune reconstitution inflammatory syndrome (IRIS), usually occurs within three months of initiation of antiretroviral treatment. It can also appear as exacerbation of tuberculosis when initiating antiretroviral treatment in HIV-infected tuberculosis patients who are already undergoing antituberculosis treatment, similar to the well documented paradoxical reactions seen in some patients without underlying HIV infection. IRIS is commonly associated with tuberculosis, although it can also occur with other pathogens.

Recommendations:
- Tuberculosis should be diagnosed and treated before initiation of antiretroviral treatment and whenever there is clinical suspicion of IRIS (Strength: A–IV).
- IRIS is not a reason to switch patients on to second-line antiretroviral treatment, although adjustment to the treatment regimen may be needed to ensure compatibility with antituberculosis treatment (Strength: A–IV).
- Health care workers should be aware of paradoxical worsening of tuberculosis on starting antiretroviral treatment, and both antiretroviral and antituberculosis treatments should be continued (Strength: A–IV).

Diagnosis of extrapulmonary tuberculosis

Context: Extrapulmonary tuberculosis is more strongly HIV-related than pulmonary tuberculosis, with a combination of the two being especially suggestive of underlying HIV-infection. HIV-related extrapulmonary tuberculosis is a WHO clinical stage 4 (advanced AIDS) diagnosis, and patients with HIV-related extrapulmonary tuberculosis often have disseminated disease and are at high risk of rapid clinical deterioration and death. The accurate diagnosis of extrapulmonary tuberculosis is complex and difficult, particularly in peripheral health facilities with limited support and diagnostic infrastructure. Simplified, standardized clinical management guidelines for most common and serious forms of extrapulmonary tuberculosis are included in this document to assist health care workers at the district hospital level in HIV-prevalent settings (see Part II below).

Recommendations:
- There should be an increased level of clinical awareness and competence in managing extrapulmonary tuberculosis at first-level health facilities, including earlier referral of patients when appropriate (Strength: A).
- In peripheral health facilities in HIV-prevalent settings, health care workers should initiate empirical antituberculosis treatment early in patients with serious illness thought to be due to extrapulmonary tuberculosis. Every effort should then be made to confirm the diagnosis of tuberculosis, including monitoring the clinical response of the patient, to ensure that the patient’s illness is being managed appropriately. If additional diagnostic tests are unavailable, and if referral to a higher level facility for confirmation of the diagnosis is not possible, antituberculosis treatment should be continued and completed (Strength: B–IV).
- Empirical trials of treatment with incomplete regimens of antituberculosis drugs should not be performed (Strength: A–I).
- If a patient is treated with empirical antituberculosis drugs, treatment should be with standardized, first-line regimens, which should be used for the entire duration of antituberculosis treatment. Empirical treatment should be stopped only if there is bacteriological, histological or strong clinical evidence of an alternative diagnosis (Strength: A).

Recording and reporting

Context: The recording and reporting of smear-negative pulmonary and extrapulmonary tuberculosis by national tuberculosis control programmes needs strengthening. Information from case-reporting should increasingly be used to inform changes in programme performance.

Recommendations:
- The 2003 recommendation that cases without smear results should be reported as smear-negative pulmonary cases should be revised (Strength: A).
- The revised standard tuberculosis recording and reporting formats should be used to gen-
erate sound case-notification and treatment outcome data for smear-negative pulmonary and extrapulmonary cases. This should inform policy and programme performance both nationally and globally (Strength: A).

**Recommendations for HIV-prevalent and resource-constrained settings**

Algorithms for the diagnosis of smear-negative tuberculosis

In the absence of rapid and simple tools to diagnose tuberculosis, the main aim of these algorithms is to assist clinical decision-making in HIV-prevalent and resource-constrained settings, to expedite the diagnostic process and minimize incorrect diagnosis and mortality. The algorithms will have significant implications for both tuberculosis and HIV/AIDS service providers in these settings, and will catalyse the integration of HIV and tuberculosis interventions at the point of service delivery. The algorithms are aimed at adult and adolescent patients presenting with cough of 2–3 weeks’ duration and differ according to the clinical condition of the patient (ambulatory or seriously ill).

**Guiding principles**

**Target group:** The newly revised algorithms (Figures 1 and 2) are targeted at adults living with HIV/AIDS and those considered to be at high risk of HIV infection on clinical and epidemiological grounds, as laid down in national and/or local policy. The diagnostic procedure for HIV-negative patients and those who are less likely to be HIV-infected should follow the codified algorithm (based on WHO’s 2003 recommendations) included in the *International standards for tuberculosis care*, 2006 (Figure 3).

**Danger signs:** The adult patient will be classified as seriously ill if one or more of the following danger signs are present:
- unable to walk unaided
- respiratory rate over 30 per minute
- fever of more than 39 °C
- pulse rate of over 120 per minute.

**AFB microscopy:** At least two sputum specimens should be taken and examined for AFB. One of the specimens should be early-morning sputum produced after an overnight sleep. One positive AFB smear will be sufficient to classify a patient as a smear-positive case if the patient is HIV-infected or if there is strong clinical suspicion of HIV infection.

**HIV testing:** HIV testing should be routinely offered along with sputum examination for AFB in HIV-prevalent settings for patients presenting with cough of 2–3 weeks’ duration. A person with unknown HIV status (e.g., because of unavailability of HIV test kits or refusal to be tested) can be classified as HIV-positive if there is strong clinical evidence of HIV infection.

**HIV assessment:** This includes clinical staging of HIV infection (see Table 2), immunological staging (CD4 count), referral for HIV care including antiretroviral treatment, long-term follow-up and chronic management, including co-trimoxazole preventive therapy. The clinical staging is important, as some patients with pulmonary tuberculosis may also have concurrent stage 4 disease requiring more rapid initiation of antiretroviral treatment.

**Clinical assessment:** This is a critical step in the diagnostic process, particularly in the absence of any bacteriological confirmation of tuberculosis. It must be based, as far as possible, on supportive investigations and sound clinical judgement in order to arrive at a correct diagnosis without undue delay and prevent excess mortality from undiagnosed tuberculosis. It is also useful for the diagnosis and management of nontuberculous conditions during all evaluations of the patient. Sound clinical judgement will be essential for: classifying the patient as ambulatory or seriously ill on the basis of danger signs; classifying the patient of unknown HIV status as HIV-positive or negative; starting the patient on broad-spectrum antibiotics or antituberculosis drugs on the basis of his/her clinical condition and presentation; assessing, managing and/or referring the patient for treatment for other diseases. Because performing these activities is part of basic clinical practice, it is not possible to be more instructive in these recommendations.

**Clinical response:** For patients in whom tuberculosis is less likely and who are treated empirically for bacterial pneumonia or *Pneumocystis carinii* pneumonia (PCP), clinical response

$^a$ The danger signs include any one of: respiratory rate >30/minute, fever >39 °C, pulse rate >120/min and unable to walk unaided.

$^b$ For countries with adult HIV prevalence rate ≥1% or prevalence rate of HIV among tuberculosis patients ≥5%.

$^c$ In the absence of HIV testing, classifying HIV status unknown as HIV-positive depends on clinical assessment or national and/or local policy.

$^d$ AFB-positive is defined at least one positive and AFB-negative as two or more negative smears.

$^e$ CPT = Co-trimoxazole preventive therapy.

$^f$ HIV assessment includes HIV clinical staging, determination of CD4 count if available and referral for HIV care.

$^g$ The investigations within the box should be done at the same time wherever possible in order to decrease the number of visits and speed up the diagnosis.

$^h$ Antibiotics (except fluoroquinolones) to cover both typical and atypical bacteria should be considered.

$^i$ PCP: Pneumocystis carinii pneumonia, also known as Pneumocystis jirovecii pneumonia.

$^j$ Advise to return for reassessment if symptoms recur.
should not automatically exclude the diagnosis of tuberculosis. Acute bacterial pneumonia or PCP may occur in patients with underlying tuberculosis and patients should, therefore, be re-evaluated for tuberculosis, particularly if respiratory symptoms persist after treatment. Follow-up assessment of these patients can take place under either tuberculosis services or HIV services, according to country-specific guidance and practice.

Algorithm for the ambulatory patient

This algorithm is used for a tuberculosis suspect without the danger signs defined above (an ambulatory patient). The diagnostic process should be expedited if the patient is HIV-positive, or likely to be so. The total number of visits for separate evaluations from the time of initial presentation to a health facility to the time of diagnosis should not exceed four. The number of days involved between evaluations will vary depending on several country-specific factors, and appropriate measures should be instituted by national and local tuberculosis and HIV authorities to minimize the time and the number of visits required to establish the diagnosis. Shortening the turnaround time for sputum smear examinations is crucial.

The following principles should be followed when applying the algorithms for the ambulatory patient in order to expedite the diagnosis of smear-negative pulmonary tuberculosis.

- **First visit:** HIV testing should be offered and AFB sputum examination should be performed. If AFB test is positive, treat for tuberculosis.

- **Second visit:** If the AFB examination is negative, the patient should be provided with all available investigations during the second visit. The second visit should ideally take place on the second day following first presentation at the health facility. The investigations include: repeated sputum AFB, sputum culture and chest X-ray. Clinical assessment is also important for deciding whether to put the patient on antituberculosis treatment at this stage. HIV assessment should also be performed and co-trimoxazole preventative therapy provided according to national guidelines.

- **Third visit:** Results of the second-visit investigations (except culture) should be available during the patient’s third visit. Patients suspected of having tuberculosis after these investigations (e.g. compatible radiograph plus symptoms) should be treated for tuberculosis. Patients who are not treated for tuberculosis should receive either a broad-based antibiotic (not a fluoroquinolone) to treat bacterial infection or treatment for PCP. HIV assessment should also be performed and co-trimoxazole preventive therapy provided according to national guidelines.

- **Fourth visit:** The patient’s response is assessed and a clinical follow-up mechanism is established (in either the tuberculosis or the HIV services). For patients with immediate response to PCP or antibiotic treatment, continued vigilance is necessary to exclude superimposed tuberculosis. Those patients with an unsatisfactory response to treatment for PCP or bacterial pneumonia should be reassessed both clinically and bacteriologically for tuberculosis.

Algorithm for seriously ill patient

A seriously ill patient with one of the danger signs should be immediately referred to a higher-level health facility. When immediate referral is not possible, the following measures should be undertaken in the peripheral health facility.

- Immediately start with broad-spectrum parenteral antibiotics for bacterial infection and perform HIV test and sputum AFB examination. Safe injection practices should be strictly followed. If the indications laid down in national guidelines are present, PCP treatment should be considered. If the HIV test is negative or there is less clinical suspicion of HIV infection, or if the national or local guidelines do not classify the area as HIV-prevalent, continue management of the HIV-negative patient according to national practice and guidelines. If the HIV test is positive, or there is high clinical suspicion of HIV infection, follow the algorithm.

a. Unexplained indicates that the condition is not explained by any other condition.
b. Assessment of body weight in pregnant women needs to take into account the expected weight gain of pregnancy.
c. Some additional specific conditions can also be included in regional classifications (e.g. reactivation of American trypanosomiasis (meningoencephalitis and/or myocarditis) in the WHO Region of the Americas and penicilliosis in Asia).
RECOMMENDATIONS FOR HIV-PREVALENT AND RESOURCE-CONSTRAINED SETTINGS

- If the diagnosis of tuberculosis is confirmed by AFB smear examination, start antituberculosis treatment. The antibiotic treatment should be continued and completed.

- If the AFB smear is negative, response to parenteral antibiotics should be assessed 3–5 days into treatment, and, if there is no improvement, antituberculosis treatment should be initiated. The initial antibiotic course should be continued and completed. HIV assessment and clinical staging should be performed. Patients should be referred to the next level of care to confirm the diagnosis of tuberculosis and for HIV care. If referral is not possible, antituberculosis treatment should be completed.

- If referral to a higher-level facility is possible, the patient should be managed as an emergency and all available investigations, including HIV testing, should be performed at one time for the diagnosis of tuberculosis.
PART II

Simplified and standardized clinical management guidelines for extrapulmonary tuberculosis
Background

One in five registered tuberculosis patients has extrapulmonary tuberculosis (8, 9, 10). The commonest forms include lymph node (especially in the neck or under the arms), pleural (usually one-sided pleural effusion) and disseminated tuberculosis (disease that is not limited to one site in the body). Pericardial and meningeal tuberculosis are less frequent forms of extrapulmonary tuberculosis that are also covered in these guidelines. About one-third of deaths in HIV-positive Africans are due to disseminated tuberculosis (11, 12, 13) but only about half of HIV-positive patients who die from disseminated tuberculosis are diagnosed before death (12, 13, 14). With the exception of lymph node tuberculosis, which can usually be confirmed through aspiration of affected lymph nodes, most patients with extrapulmonary tuberculosis are managed without bacteriological or histological confirmation (15). Therefore, it is important for health care workers to have simplified, standardized guidelines for the prompt diagnosis and management of extrapulmonary tuberculosis.

Target audience

These guidelines are intended to assist the prompt diagnosis and management of extrapulmonary tuberculosis by physicians and other clinicians working in district hospitals of HIV-prevalent and resource-constrained settings as part of national tuberculosis control programme activities.

Diagnosis and management

The indications for suspected extrapulmonary tuberculosis and the key signs to look for in the commonest forms of the disease are summarized in Figure 4. Table 3 summarizes the essential investigations required for diagnosis and key steps for immediate management of suspected extrapulmonary tuberculosis cases. For a patient with suspected extrapulmonary tuberculosis who is started on antituberculosis treatment without bacteriological or histological confirmation, the clinical response to treatment should be assessed after one month. If there is no improvement, a clinical reassessment should be performed and an alternative diagnosis sought.

HIV testing should be offered to all patients suspected of extrapulmonary tuberculosis. This is because HIV-related extrapulmonary tuberculosis is an indication for early commencement of antiretroviral treatment (clinical stage 4 of HIV disease). For HIV-related extrapulmonary tuberculosis, the following interventions should be carried out:

- refer for HIV care or start antiretroviral treatment according to national guidelines
- start co-trimoxazole preventive therapy
- remain vigilant for clinical deterioration of extrapulmonary tuberculosis after the start of antiretroviral treatment (immune reconstitution inflammatory syndrome – IRIS) and take appropriate measures.

Tuberculous lymphadenitis

Tuberculous lymphadenitis should be suspected in any patient with enlarged lymph nodes that are firm, asymmetrical, more than 2 cm in diameter, or where a node has become fluctuant or developed a fistula over several months. It most commonly affects the nodes in the neck (cervical region) and is difficult to distinguish clinically from other causes of enlarged nodes, such as reactive and/or HIV-related lymphadenopathy, malignancies and other lymph node infections, which are also common. Therefore, needle aspiration using recommended techniques (see box “Guidelines for lymph node aspiration” below) should be carried out at the first outpatient visit for all patients.

Needle aspiration with cytology and tuberculosis microscopy of aspirated material has a high diagnostic yield, with confirmation of over 85% of patients with tuberculous lymphadenitis in some (16, 17, 18, 19) but not all (20) reports, suggesting that the technique may be important. If a fistula has formed, then microscopy of discharging pus is likely to show AFB. Cytology, if available, can identify most other important causes of enlarged lymph nodes, including
**Suspect ETB in patients with**

Cough for two weeks or more or
- Unintentional weight loss with
  - Night sweats and
  - Temperature >37.5 °C or feels feverish
- Breathlessness (effusion/pericarditis) or
- Enlarged glands in neck/armpit or
- Chest X-ray
  - Miliary or diffuse shadowing
  - Large heart (especially if symmetrical and rounded)
  - Pleural effusion
  - Enlarged lymph nodes inside the chest
- Chronic headache or altered mental state

**Suspect disseminated tuberculosis in all people living with HIV who experience rapid or marked weight loss, fever and night sweats**

**Establish HIV status if ETB is suspected**

- Advise and arrange for rapid HIV testing if status is unknown or last test was negative
- Explain that this will affect the way that this illness is investigated and treated
- Discuss the need for antiretroviral treatment if HIV-related tuberculosis is diagnosed
- If consent is given, try to arrange testing on the same day

**Look and listen for**

- Lymph nodes swelling in the neck or armpits (if present with other types of ETB it may provide the only way to confirm the diagnosis)
  **Possible tuberculosis lymphadenitis**
- Signs of fluid in the chest
  - Absent breath sounds
  - Reduced chest wall movement
  - Dull to percussion
  **Possible tuberculosis pleural effusion**
- Signs of fluid around the heart
  - Heart sounds distant
  - Swollen legs and/or abdomen
  - Neck and hand veins distended with arm held above the shoulder
  **Possible tuberculosis pericarditis**
- Signs of meningitis
  - Neck stiffness
  - Confusion
  - Abnormal eye movements
  **Possible tuberculosis meningitis**
malignancies and other infections. Follow-up to receive the results should be within seven days. If the aspirate does not yield a diagnosis, then excision biopsy for gross examination, Ziehl-Neelsen microscopy, mycobacterial culture and, if available, histological examination can be considered. However, antituberculosis treatment should be started immediately if:

- the patient is HIV-infected and has clinical features of disseminated tuberculosis (such as marked weight loss, rapid clinical deterioration or multiple sites of suspected tuberculosis) or
- tuberculous lymphadenitis is considered the most likely clinical diagnosis, but logistic or economic barriers are likely to delay excision biopsy for two weeks or longer.

**Pleural effusion**

Tuberculosis is the likely cause of unilateral pleural effusion in countries with a high tuberculosis burden. It was the diagnosis reached in 95% of patients in two recent case-series from Uganda and Zimbabwe (21, 22). Pleural effusion is the most common form of HIV-related extrapulmonary tuberculosis, with high mortality (over 20%) in the first two months of antituberculosis treatment (21, 22).

The following key steps should be undertaken.

- The management of tuberculous pleural effusion should aim at starting antituberculosis treatment and identifying underlying HIV infection without delay. Pleural biopsy has a high diagnostic yield (21, 22), but is not recommended because it is unnecessarily invasive and has the potential to introduce diagnostic delay.
- Suspected pleural effusion should be confirmed by chest radiography and immediate aspiration of fluid whenever possible (see Table 3), placing aliquots of the aspirate into one plain and two anticoagulated tubes.
- Treatment with broad-spectrum antibiotics is not required before antituberculosis treatment in patients with unilateral effusions if the pleural fluid is clear and clots on standing, unless there is clinical concern about bacterial pneumonia.
- Patients with unusual findings, such as bilateral effusions and cloudy or bloody aspirates, should undergo the additional investigations detailed in Table 3. If visible clots form in

---

**Guidelines for lymph node aspiration**

Equipment needed: topical antiseptic, gloves, 5 ml syringe and 18 to 21 gauge needle,* 3 glass microscopy slides, cytological fixative (e.g. absolute alcohol or methanol) if cytology available

**Steps**

1. Prepare the microscopy slides with the patient’s name and identification number.
2. Apply a topical antiseptic to the skin overlying the enlarged lymph node.
3. Attach the needle and expel all air from the syringe.
4. With the nondominant hand, take the gland between the thumb and the index finger to make it stand out and hold it steady.
5. Taking the syringe in the dominant hand, insert the needle through healthy skin into the centre of the node or at the point of maximum fluctuance, and pull back on the syringe piston. If no aspirate is obtained, move the needle in and out of the centre of the node while pulling back on the syringe piston. Gently compress the node with the nondominant hand and revolve the needle in both directions. Small amounts of lymph node tissue will collect in the needle and needle hub, even if there is no visible aspirate inside the syringe.
6. Withdraw the needle and syringe and spread aspirate onto each slide. It may be necessary to disconnect the syringe and introduce a small amount of air in order to expel the contents. A separate aspirate may be needed for each slide.
7. Allow slides to air-dry. If pus is obtained, send one slide for Gram stain and one for tuberculosis microscopy. If no pus is obtained, then send both slides for tuberculosis microscopy.
8. If available, spray the remaining slide with cytological fixative, and send for cytology when dry.

* Reported yields are better with larger needle sizes (18 or 19G: wide-needle aspiration), but fine-needle aspiration with a standard phlebotomy (21G) needle can be used if that is all that is available. Lymph node needle-core biopsy is an acceptable alternative for facilities with appropriate equipment.

a KS-Kaposi’s sarcoma
b The aspirate should be put in a plain tube (with no anticoagulant) in order to observe its appearance and clotting. A second aliquot should be placed into an anticoagulated tube, so that a differential white blood cell count and protein determination can be requested if there are any findings to suggest a non-tuberculosis diagnosis.
the aspirate within a few minutes of its being placed into a plain tube (no anticoagulant), then this confirms the high protein content of the fluid, which indicates tuberculosis. No further investigations are needed if the aspirate is clear and straw-coloured and there are no other features suggestive of a diagnosis other than tuberculosis.

- Failure of the aspirate to clot does not exclude tuberculosis, and such patients can still be started on antituberculosis treatment immediately if there are no other unusual findings (Table 3), but laboratory analysis of fluid is needed to determine the protein content (expect \(\geq 30\) g/L in patients with a tuberculous effusion, but it can be lower in very wasted patients) and differential cell count (expect \(\geq 50\%\) lymphocytes in a tuberculous effusion). The aim should be to start antituberculosis treatment within seven days unless another diagnosis has been made.

- If thoracentesis is not available, antituberculosis treatment should be started immediately, particularly if the patient is HIV-infected, unless there are clinical or radiological features suggestive of a diagnosis other than tuberculosis.

Other forms of extrapulmonary tuberculosis

Most patients with other forms of extrapulmonary tuberculosis present in a sufficiently characteristic way to allow antituberculosis treatment to be started without attempting to confirm the disease bacteriologically or histologically. Although extrapulmonary tuberculosis can be confirmed in the majority of patients through invasive biopsy and/or multiple cultures, these investigations are not routinely recommended, as they are expensive and may result in lengthy diagnostic delays that can reduce the chances of a good treatment response (19).

Taking specimens for culture increases the chances that tuberculosis will be confirmed, but treatment should not generally be delayed until culture results are available. Instead, antituberculosis treatment should be started promptly, if indicated after the essential investigations and assessments shown in Table 3. The attending health care worker should carefully consider the need for additional investigations and treatment (such as antibiotics) if a diagnosis other than tuberculosis is suspected. However, it is not necessary to give broad-spectrum antibiotics routinely before considering antituberculosis treatment.

Tuberculosis treatment should be started as soon as other common conditions that can cause a similar clinical picture have been excluded (see Table 3 for essential investigations) in patients presenting with the following conditions.

- Pericardial effusion: tuberculosis is the cause of about 90% of HIV-related pericardial effusion, but a lower percentage (50% to 70%) of pericardial effusions in HIV-negative individuals (23, 24, 25).

- Meningitis with features of the cerebrospinal fluid suggestive of tuberculosis (see Table 3).

- Suspected disseminated tuberculosis in febrile patients presenting with HIV wasting syndrome. High rates of undiagnosed disseminated tuberculosis have been consistently identified in febrile, HIV-positive inpatients and in postmortem series from several countries (11, 12, 13, 14, 26, 27, 28, 29, 30).

Patients with clinical features or investigation results that suggest a diagnosis other than extrapulmonary tuberculosis (listed in Table 3) need more extensive investigation before antituberculosis treatment is considered, but with the aim of keeping diagnostic delays to a minimum.

Adjuvant corticosteroids

Corticosteroids started at the time of tuberculosis diagnosis and given for the first two months of treatment significantly improve survival from tuberculous meningitis in HIV-negative patients, and are now recommended for such patients (31). For other forms of extrapulmonary tuberculosis and for HIV-related tuberculous meningitis, the effects of steroids are still uncertain. The results of small trials on tuberculous pericarditis are promising (32). There
appears to be no benefit in adding steroids to the treatment of tuberculous pleural effusion, with some suggestion of possible harm to HIV-positive patients (33). Recommendations may change when the results of larger randomized clinical trials become available within the next few years.

ANNEX
Protocol for operational evaluation of the revised recommendations and algorithms for improving the diagnosis of tuberculosis in HIV-prevalent settings
Background

In 1991, WHO first published guidelines for national tuberculosis control programmes that included criteria for the diagnosis of smear-positive and smear-negative pulmonary and extrapulmonary tuberculosis. These were subsequently revised in 1997 and 2003. In response to concerns that the 2003 guidelines (1) did not adequately reflect the diagnostic and treatment challenges of HIV-associated tuberculosis, WHO has revised its recommendations for the diagnosis of tuberculosis in HIV-prevalent settings.

Major changes between the revised recommendations presented in this document, and the previous guidelines (2003) are as follows.

1. The revised 2006 guidelines apply only to:
   (a) patients suspected of having tuberculosis and living in settings (geographical area or health facility) with an HIV prevalence >1% in pregnant women or an HIV-prevalence ≥5% in tuberculosis patients.
   (b) patient’s age >15 (guidelines for childhood tuberculosis are separate).
   (c) note that, for all other populations, the existing guidelines laid down in the International standards for tuberculosis care (2) should be followed.

2. All tuberculosis suspects should be routinely offered HIV counselling and testing. This differs from the existing WHO recommendation that these should be offered only to tuberculosis patients.

3. A “trial” of antibiotics is not required to diagnose smear-negative pulmonary tuberculosis.

4. Two sputum specimens, with one collected in the morning, are sufficient for the initial diagnostic evaluation of tuberculosis in HIV patients. This differs from the 2003 WHO recommendation that “at least” three specimens should be AFB-negative before diagnosing smear-negative pulmonary tuberculosis.

5. A patient is considered to have smear-positive tuberculosis if at least one specimen is positive for AFB.

6. Sputum culture for Mycobacterium tuberculosis should be performed in patients who are sputum smear-negative to confirm the diagnosis of tuberculosis and improve the quality of care.

In the absence of complete evidence, the recommendations are based on consensus and iterative global expert opinion in order to respond to the catastrophe posed by the HIV epidemic. They should, therefore, be implemented in HIV-prevalent settings. However, it is equally important to build up the evidence base simultaneously, in settings where this is possible, in order to assess the effectiveness and feasibility of the guidelines and thus inform changes in policy and practice.

Objectives of the evaluation

The primary intent of the evaluation is to measure the performance of tuberculosis programmes that implement the revised recommendations and generate knowledge for improving those specific programmes. The evaluation involves measuring different indicators of input, process, output, outcome and impact in settings that implement the revised recommendations and comparing them with settings that have not implemented the recommendations. The evaluation provides information for international and national health policy-makers and public health officials about the strengths and weaknesses of the revised guidelines in order to inform changes in international and national policy and practice. Therefore, the evaluations should be conducted in close collaboration with national tuberculosis and HIV control programmes in the countries concerned.

Purpose of the protocol

This protocol provides generic guidance on conducting evaluations of the revised recommendations to improve the diagnosis of tuberculosis in HIV-prevalent settings. It is intended to standardize the minimum information that needs to be generated by the evaluation in order to inform changes in policy at both national and global levels. The protocol will also provide a flexible platform for research groups and inter-
estimated stakeholders to evaluate these recommendations and, at the same time, enable them to contribute to changes in policy and improvements in programme performance both globally and nationally.

**Hypotheses**

Compared with settings implementing the 2003 guidelines (existing practice), settings implementing the revised guidelines of 2006 are expected to display the following characteristics.

1. A larger proportion of tuberculosis suspects diagnosed with smear-negative tuberculosis.
2. A smaller proportion of smear-negative pulmonary and extrapulmonary tuberculosis patients who die before treatment is completed.
3. A smaller proportion of tuberculosis suspects who die before completion of the diagnostic evaluation or within two months of initial contact with health services for tuberculosis diagnosis.
4. A shorter time-lag between onset of cough and treatment for tuberculosis, and between date of initial contact with health services for tuberculosis diagnosis and beginning of antituberculosis treatment.
5. A larger proportion of patients and providers satisfied with the speed and quality of diagnostic services.
6. A larger proportion of patients with a complete diagnostic evaluation, including two sputum smears, chest radiography and sputum culture.

**Overall design**

The suggested overall design for the study is a prospective, observational study. The justification for this approach is as follows.

1. Prospective: Historical data, such as medical chart reviews, could be used to compare outcomes, but such data may lack the detail required to answer important public health questions about patient and provider satisfaction or to compare costs. Similarly, in many countries, rapid advances are occurring in HIV care and treatment, which could affect the frequency of diagnosis of tuberculosis, the types of disease diagnosed and the outcomes of patients treated for tuberculosis. Conducting this study prospectively will help control for these factors.

2. Observational: The study will involve no experimental diagnostic tests or medicines. Clinical care will be implemented according to existing national guidelines. Even if a country wanted to implement the revised guidelines nationwide, implementation would be likely to occur in stages. The observational study design therefore allows for both implementation of guidelines and a quasi-experimental assessment of impact. For the reasons described above, a randomized clinical trial...
is not an ethically appropriate design. Involving multiple centres will both be useful and allow for comparison of the impact on programmes.

Study description

A “setting” denotes either an individual health facility or an administrative area (e.g. district) that contains multiple health facilities. Settings will be included in the study only if they are already following the WHO-recommended Stop TB strategy, which includes standardized recording and reporting of tuberculosis cases, and if they are implementing either the existing (2003) or the revised (2006) recommendations. The settings implementing the revised recommendations should also be required to implement the revised recording and reporting formats according to national guidelines. (The relevant documents are available from the WHO website: http://www.who.int/tb/err/en/index.html). Ideally, settings will be allocated in a concealed, randomized process; but because the study is being conducted in a programme context, other factors may need to be considered when selecting sites, including availability of personnel, infrastructure and budget. For example, the availability of necessary tests and services (e.g. HIV testing, chest X-ray, sputum culture, etc.) would affect the selection of an intervention site.

Likewise, it may not be possible to select non-intervention sites randomly. There may be substantial variations in practice across and within settings that need to be considered for the selection. In those countries that have already adopted the revised guidelines as their national guidelines, those settings which have not implemented the revised guidelines for the duration of the evaluation may be selected as non-intervention sites. The ideal nonintervention site will have a standardized approach to tuberculosis diagnosis: its practice should be consistent with national guidelines and, if possible, with the 2003 WHO guidelines.

Before data collection begins, both intervention sites and nonintervention sites should undergo training in conducting the evaluation of the revised guidelines. For intervention sites (i.e. sites implementing the revised guidelines), all clinicians (physicians, clinical officers, nurses and other clinical staff) will receive training on the revised guidelines, basic diagnosis and management of tuberculosis and HIV, and completion of study documents. Supplies and equipment necessary for the implementation of the revised guidelines will be installed and relevant staff trained in their use. To reduce the potential bias in study outcomes that may be associated with such training, nonintervention sites will undergo similar training focusing on the 2003 guidelines.

Suggested studies

Within each setting (intervention and nonintervention), a number of evaluations will be conducted to measure input, process, output, outcome and impact of the revised guidelines. These suggested studies can be conducted either as independent studies or as part of a larger study, depending on the local context and the interests of research groups. Table A1 below describes the types of study and the indicators they will measure.

Study 1: assessment of costs

A standardized instrument to measure costs should be developed. The purpose of this instrument should be to measure the cost of the human resources development and infrastructure required to implement the revised guidelines. As far as possible, identical information will be obtained from the sites implementing the 2003 guidelines, in order to permit an estimate of costs associated with routine practice. The study instrument will be also used, if necessary, to abstract data from financial records.

Minimum cost components to be measured in this instrument should include costs related to: training, study materials, personnel time (including health care workers and trainers), transportation of persons and specimens, construction, equipment, supplies, reagents and consumables, standard diagnostic procedures (e.g. microscopy, radiography, culture, HIV testing), antituberculosis treatment, antibiotics prescribed for bacterial infection.

No statistical sampling will be performed for this study. No informed consent will be obtained, because no personal, sensitive or health-related information will be collected.

Study 2: patient satisfaction survey

A survey of tuberculosis suspects will be conducted to determine their satisfaction with the diagnostic process in facilities implementing the revised guidelines, compared with those implementing the 2003 guidelines.

Case definition: A pulmonary tuberculosis suspect will be defined as any person not currently receiving antituberculosis treatment and without a current diagnosis of tuberculosis, with cough >2 weeks duration or sputum collected for AFB smear microscopy at the request of a clinician.

Inclusion criteria: All persons meeting the case definition who seek health care at a participating facility during the enrolment period, who agree to be contacted one month after their first diagnostic evaluation as a tuberculosis suspect.

Exclusion criteria: Persons not meeting the case definition and inclusion criteria, or persons meeting both the case definition and inclusion criteria who are aged <15 years, cannot be contacted or refuse to participate, or who die before they can be interviewed.

Estimated number of participants and sampling: At least 200 persons in total will be interviewed, 100 from intervention and 100 from nonintervention sites over a six-month period. This sample size and study period are suggested for convenience and practicality. However, more accurate sample-size estimations and study periods may be employed, based on the local tuberculosis and HIV epidemiology. If the estimated number of suspects is >200, an appropriate and uniform method for sampling the population will be chosen for both intervention and nonintervention sites.

Enrolment procedure:
1. Persons presenting at the health care facility will be identified as tuberculosis suspects using routine criteria for that facility, and a register will be maintained of all tuberculosis suspects (see below).

2. Study staff will present tuberculosis suspects with a consent card or form, informing them that a survey is being conducted about patient satisfaction. Staff will explain to patients that they will be asked to provide contact information so that they can be contacted in one month to determine how satisfied they were with their tuberculosis evaluation. Patient consent or refusal to participate in the survey will be recorded in the register.

3. After two months, study staff will review the list of consenting patients and, according to the established sampling criteria, attempt to contact tuberculosis suspects who were evaluated during the first month of the study. Subsequent reviews of the list will occur every month.

4. Study staff will attempt to contact patients to perform the survey. The survey may be administered by telephone or in person, depending on the logistics at each site. If a patient cannot be contacted, patients will continue to be selected from the list of consenting tuberculosis suspects, following the same selection procedure. If that procedure cannot be followed, an alternative procedure for randomly selecting patients will be identified; that procedure will be documented.

Consent: Patients will be asked to consent to participating in the survey. They have to be assured that consenting or refusing to participate in the survey will have no effect on the treatment they receive. Consent will be verbal and brief, because no sensitive health care information is being collected and such surveys are part of routine health care practice in many settings. Contact information for tuberculosis suspects, such as address or telephone, may already be collected routinely for financial, administrative or public health reasons. In that situation, individual sites will decide whether it is ethically appropriate to use that information for selecting tuberculosis suspects for the satisfaction survey.

Study instruments: A study instrument will be developed to meet the needs of the site concerned. Minimum data elements to be included are patient ratings of: speed of service; comprehensiveness of service; affordability of service; perception of attention to individual needs; overall satisfaction with service.
Study 3: Health Care Provider Survey

A survey of health care providers will be conducted to determine their satisfaction with the clinical practice guidelines.

Case Definition: A health care provider will be defined as any person employed by a health care facility and involved in the clinical care of tuberculosis patients.

Inclusion Criteria: All health care providers, including nurses, clinical officers, physicians or other care providers, who work in facilities participating in this study during the study period and are involved in the diagnosis or treatment of tuberculosis.

Estimated Number of Participants and Statistical Sampling: The number of participants will vary depending on the size of the participating facilities. If possible, all health care providers will be studied and there will be no statistical sampling.

Enrolment Procedure:
1. A supervisor at the health care facility will prepare a list of all health care providers meeting the inclusion criteria.
2. At the beginning of the study period, the questionnaire will be sent to all health care providers.
3. At the end of the study period (i.e. after six months), the same questionnaire will be readministered.

Consent: Health care providers will be asked to consent to participating in the survey. Consent will be written. It will be brief, because no sensitive information is being collected.

Study Instruments: A study instrument will be developed. Minimum data elements will include: basic questions about tuberculosis knowledge, attitudes and practices; basic questions about HIV knowledge, attitudes and practices; ranked measurement of availability and quality of smear microscopy and chest radiography; patient perception of the diagnostic process; availability, speed, quality; individual perception of current guidelines in the facility for smear-negative tuberculosis diagnosis; feasibility, speed, quality, overall satisfaction; open-ended questions about satisfaction with the process for diagnosis of tuberculosis in HIV-infected patients.

Study 4: Tuberculosis Suspect Outcome Review

Case-report forms will be completed for all tuberculosis suspects to measure programme outputs from implementation of the clinical practice guidelines. Depending on existing practices at participating health facilities, it is possible that no new data collection instruments or procedures, other than those already used routinely, will be needed for this component of the study.

Case Definition: The definition of a tuberculosis suspect is given in the section “Patient satisfaction survey” above.

Inclusion Criteria: All persons meeting the case definition who seek health care at a participating facility during the enrolment period.

Exclusion Criteria: None.

Estimated Number of Participants and Statistical Sampling: The number of participants will vary depending on the size of participating facilities. The minimum sample size needed to demonstrate a difference between facilities implementing the 2003 guidelines (i.e. existing practice) and the 2006 guidelines will be calculated on the basis of the epidemiological situation and baseline programme performance in participating sites.

Enrolment Procedure:
1. Persons presenting at the health care facility will be identified as tuberculosis suspects using routine criteria for that facility and a register will be maintained of all tuberculosis suspects.
2. Patients will be informed generally by written signs or posters that the clinic is participating in a study, but individual patients will not be asked to provide informed consent (see justification below).
3. Case-report forms will be collected for all tuberculosis suspects, using a separate study form or a modification of existing clinical records (see below).
4. For patients who do not complete the diagnostic evaluation, health care facilities will use existing contact information (e.g. telephone number, address, treatment supporters) to contact patients two months after their initial contact with health services for tuberculosis diagnosis to determine whether they are still alive and, if they have died, when death occurred.

**Consent:** Tuberculosis control programmes routinely collect and review the medical records of tuberculosis suspects to assess programme performance, e.g. measuring the number of sputum specimens collected. This process does not involve informed consent, because no patient identifiers are collected and data are used specifically to evaluate and improve programme performance. Although the number of data components being reviewed is likely to be greater than usual, the process and intent are similar.

**Study instruments:** Health care facilities routinely collect standard data about patients. The extent of such routine data collection varies depending on the facility and provider practice. For this evaluation, health care forms will be modified (or nationally revised recording and reporting formats will be used) to include the following minimum data elements, or a separate study-specific form will be used, depending on each site’s preference: unique tuberculosis suspect identifying number; age; sex; district; date when first presented at clinic; cough; date when cough began; other symptoms; HIV diagnosis (status: positive/negative/unknown and date of HIV diagnosis); sputum smears (date, results); sputum culture (date, result); chest radiograph (date, findings); antibiotics taken before visit and after initial visit (prescribed/self-procured/name of antibiotic and dosage); date of tuberculosis diagnosis; final diagnosis (if not diagnosed with tuberculosis) and date of last evaluation in clinic.

**Study 5: tuberculosis patient outcome review**

Case-report forms will be completed for all tuberculosis patients to measure programme outcome and impact of implementation of the clinical practice guidelines. Depending on existing practices at participating health facilities, it is possible that no new data collection instruments or procedures, other than those already used routinely, will be needed for this component of the study.

**Case definition:** A tuberculosis patient will be defined as any person diagnosed with tuberculosis and advised to begin antituberculosis medication. The definitions of smear-positive vs smear-negative tuberculosis will depend on the guidelines being implemented at the study site (the 2003 guidelines – i.e. existing practice – or the 2006 guidelines).

**Inclusion criteria:** All persons meeting the case definition who are diagnosed with tuberculosis at a participating facility during the enrolment period.

**Exclusion criteria:** Patients will be excluded if they are registered as “transfer in”, “treatment after default”, “treatment after failure” or “chronic”.

**Estimated number of participants and statistical sampling:** The number of participants will vary depending on the size of participating facilities. The minimum sample size needed to demonstrate a difference between facilities implementing the 2003 guidelines (i.e. existing practice) and the 2006 guidelines will be calculated on the basis of the epidemiological situation and baseline programme performance in participating sites.

**Enrolment procedure:**

1. Patients will be registered and begin antituberculosis treatment following the routine practice at the health care facility concerned.

2. Patients will be informed generally by written signs or posters that the clinic is participating in a study, but individual patients will not be asked to provide informed consent (see justification below).

3. Data from the tuberculosis register and patient records will be abstracted during the course of the study. No specific procedures will be used for enrolment or withdrawal from the study, since patients will be treated according to routine practice.
Consent: See section on “Consent” under Study 4 above.

Study instruments: Health care facilities routinely collect standard data about patients. The extent of such routine data collection varies depending on the facility and provider practice. If necessary, health care forms will be modified to include the following minimum data elements, or a separate study-specific form will be used, depending on each site’s preference: unique, random tuberculosis suspect identifying number; tuberculosis patient registration identifying number; tuberculosis registration date; HIV clinical stage; CD4 count; dates and dosage of co-trimoxazole prescribed; dates, dosage and regimen of antiretroviral treatment; antituberculosis treatment regimen; presence or absence of adverse events during antituberculosis treatment; sputum conversion result (if smear-positive at the beginning of treatment); treatment outcome and date of treatment outcome.

Study timeline
The exact duration of the study will depend on the number of settings involved, the total volume of patients in each setting and local formalities (such as ethical clearance) of the stakeholders carrying out the evaluation. Expedited implementation of the evaluation is highly recommended and desirable.

Reimbursements and incentives
Participants will receive no formal reimbursements or incentives as part of this study, although sites are permitted to provide modest incentives, such as food, for patients who attend follow-up visits, if such incentives are part of routine care.

Data handling and analysis
Statistical methodology, data collection, planned tables and figures may vary depending on the investigators conducting the evaluation. Public health programmes related to tuberculosis and HIV are changing rapidly throughout the world. The study is designed as an observational study to evaluate the impact of implementing the revised recommendations, but other changes may occur in the health system at the same time, e.g. wider availability of antiretroviral treatment or active case-finding for HIV or tuberculosis that identifies patients at an earlier stage of either disease. Such events will need to be considered when interpreting findings from the studies.

Identifying, managing and reporting adverse events
Adverse events are common during treatment of HIV-associated tuberculosis, including adverse drug reactions, hospitalization and death. As part of routine public health practice, tuberculosis control programmes maintain direct communication with patients throughout the course of treatment. During this observational study, such events will be handled according to routine public health and clinical practice. Participating study sites are all public facilities to which the patients have access because they have been registered for antituberculosis treatment. Otherwise, patients will not be exposed to any physical or psychological risks beyond those normally encountered during routine clinical care.
